TorC vs ΛCDM is prior-dominated — DESI DR2 BAO, 1000 live points

All five have $|\Delta \ln Z| < 1$: **inconclusive** on the Jeffreys scale. The data do not distinguish the models, so the Bayes factor is set by the prior on ς — it even changes sign.
Within the exponential family $\ln Z$ falls monotonically with λ — the Occam factor — and passes through *exact parity* at $\lambda = 1$ ($\Delta \ln Z = -0.03 \pm 0.14$).
$\langle \ln L \rangle$ is flat to 0.05 across all five: the fit never changes, only the cost of locating the posterior inside the prior. The uniform prior is a different *shape*, not just a width, and does not lie on the trend.
The Bayes factor runs from 1.25:1 *for* TorC to 2.06:1 *against* depending on the prior alone.
The power law $\pi(\varsigma) = 1/\varsigma^2$ — the ratio of two unit exponentials — carries no free scale, so it is the one line here that needs no justifying choice: $\Delta \ln Z = -0.29 \pm 0.14$, 1.33:1 for ΛCDM, still inconclusive.
